7 PRECURSORS AND INDIRECT EMISSIONS

Users are expected to go to Mapping Tables in Annex 1, before reading this chapter. This is required to correctly understand both the refinements made and how the elements in this chapter relate to the corresponding chapter in the 2006 IPCC Guidelines.

7.1 INTRODUCTION

This chapter addresses the calculation of emissions of precursors of greenhouse gases and of indirect emissions that have not been addressed in Volumes 2-5 and that may be reported in greenhouse gas inventories.

Although they are not included in global warming potential-weighted greenhouse gas emission totals, direct emissions of carbon monoxide (CO), nitrogen oxides (NOx), non-methane volatile organic compounds (NMVOCs), and sulphur dioxide (SO2) are also reported in greenhouse gas inventories. Carbon monoxide, NOx and NMVOC as well as CH4 in the presence of sunlight contribute to the formation of the greenhouse gas ozone (O3) in the troposphere and are therefore often called ‘ozone precursors’. Furthermore, NOx emission plays an important role in the Earth’s nitrogen cycle and is an aerosol precursor. Sulphur dioxide emissions lead to formation of sulphate particles, which also play a role in climate change. Ammonia (NH3) is an aerosol precursor with increasing contribution to ambient particulate matter concentrations in several regions, in part due to decreasing SO2 emissions. The majority of the carbon emitted in the form of non-CO2 species (i.e., CH4, CO, and NMVOCs) eventually oxidizes to CO2 in the atmosphere and this amount can be estimated from the emissions of these non-CO2 gases.

The guidance of this chapter is consistent with the use of any radiative forcing metric (e.g., Global Warming Potential or Global Temperature change Potential) included in assessment reports of the IPCC so far and follows the principle to avoid double counting (see Section 7.2.1.5). However, it does not provide guidance to estimate the overall radiative forcing resulting from emissions of greenhouse gases, precursors and indirect emissions.

Section 7.2 addresses the estimation and reporting of the precursors for national inventories. The methodologies for ambient air quality emission inventories have been elaborated in detail in the EMEP1/EEA2 Emission Inventory Guidebook (Guidebook), and these methodologies for CO, NOx, NMVOCs, and SO2 emissions are referenced in this chapter rather than to be included in the 2006 IPCC Guidelines. Exceptions are for sources not well covered by the Guidebook.

Section 7.3 addresses nitrous oxide (N2O) emissions that result from the deposition of the nitrogen emitted as NOx and NH3. Nitrous oxide is produced in soils through the biological processes of nitrification and denitrification. Simply defined, nitrification is the aerobic microbial oxidation of ammonium to nitrate and denitrification is the anaerobic microbial reduction of nitrate to nitrogen gas (N2). Nitrous oxide is a gaseous intermediate in the reaction sequence of denitrification and a by-product of nitrification that leaks from microbial cells into the soil atmosphere. One of the main controlling factors in this reaction is the availability of inorganic nitrogen in the soil and therefore deposition of nitrogen resulting from NOx and NH3 will enhance emissions. Nitrous oxide emissions will also be enhanced if nitrogen is deposited in the ocean or in lakes. For this reason, the 2006 IPCC Guidelines include guidance for estimating N2O emissions resulting from nitrogen deposition of all anthropogenic sources of NOx and NH3. Only agricultural sources of nitrogen were considered in the Revised 1996 IPCC Guidelines (IPCC 1997).

Guidance is provided in Section 7.3 on estimating N2O emissions from atmospheric deposition resulting from all categories except agricultural soil management and manure management. Section 7.3 provides information on NOx emissions. Countries may use national methodologies to estimate emissions of NH3 not originating from agriculture. NH3 emissions are also covered in the EMEP/EEA Emission Inventory Guidebook.

7.2 PRECURSOR EMISSIONS

No refinement.

---

1 Cooperative programme for the monitoring and evaluation of the long-range transmission of air pollutants in Europe (EMEP).

2 Up until 2007 this EMEP/EEA Guidebook was formally called the EMEP/CORINAIR Emission Inventory Guidebook.
Chapter 7: Precursors and Indirect Emissions

7.2.1 Inventory of precursors

7.2.1.1 Energy

For most countries, road transportation will be a major source of NO\textsubscript{x}, CO, and NMVOC emissions. Public electricity and heat production will likely be the major source of SO\textsubscript{2} emissions in countries where coal is used extensively, and also an important source of NO\textsubscript{x} emissions. Industrial combustion will also be a source of SO\textsubscript{2}, NO\textsubscript{x} and CO emissions and residential combustion a source of CO emissions. Oil production will likely be a source of NMVOC, NO\textsubscript{x}, and, CO emissions in countries that produce oil and gas.

Most NO\textsubscript{x} emissions resulting from fuel combustion are typically ‘fuel-NO\textsubscript{x}’ that is formed from the conversion of chemically bound nitrogen in the fuel. The content of nitrogen in different fuel varies. Depending on the combustion temperature, thermal-NO\textsubscript{x} and prompt-NO\textsubscript{x} can also be formed from nitrogen contained in the combustion intake air (e.g., in pulverized coal combustion).

Carbon monoxide and NMVOCs are generated during under-stoichiometric combustion conditions and are dependent on a variety of factors, including fuel type and combustion conditions.

Emissions of sulphur oxides (SO\textsubscript{x}) are primarily related to the sulphur content of the fuel, although some sulphur can be retained in the ash. Abatement in stationary and mobile (e.g., marine) combustion can reduce the amount emitted; desulphurization of fuels can reduce SO\textsubscript{2} emissions in transport related emissions.

7.2.1.2 Industrial processes and product use

No refinement.

7.2.1.3 Agriculture, Forestry and Other Land Use

The burning of crop residues emits NO\textsubscript{x} as does the addition of nitrogen to the soils from nitrogen fertilizers and other nutrients. Carbon monoxide and SO\textsubscript{2} are emitted when biomass is burned. The primary sources of the NMVOC emissions are burning of crop residues and other plant wastes, and the anaerobic degradation of livestock feed and animal excreta. Plants, mainly trees (e.g. oil palm trees) and cereals, also contribute to NMVOC concentrations in the atmosphere.

The EMEP/EEA Guidebook does not fully cover emissions from burning of biomass, therefore additional guidance is given in Agriculture, Forestry and Other Land Use (AFOLU) Volume, Chapter 4, Section 4.2.4 for Non-CO\textsubscript{2} emissions from biomass burning from forest, Chapter 5, Sections 5.2.4 and 5.3.4 for Non-CO\textsubscript{2} emissions from biomass burning in Cropland, and Chapter 6, Sections 6.2.4 and 6.3.4 for Non-CO\textsubscript{2} emissions from biomass burning in Grassland (CO, CH\textsubscript{4}, N\textsubscript{2}O, NO\textsubscript{x}). Biomass burning when forest and grasslands are converted to other uses, forest fires, and biomass burning due to forest management practices are discussed in these chapters of Volume 4 for AFOLU sector.

7.2.1.4 Waste

Open burning, as well as incineration of municipal and other solid wastes and sludge from wastewater treatment, produces emissions of NO\textsubscript{x}, CO, and SO\textsubscript{2}. NMVOC emissions can originate from wastewater treatment plants and solid waste disposal on land.

7.2.1.5 Carbon emitted in gases other than CO\textsubscript{2}

The 2006 IPCC Guidelines estimate carbon emissions in terms of the species that are emitted. The majority of the carbon emitted in the form of non-CO\textsubscript{2} species (i.e., CH\textsubscript{4}, CO, and NMVOCs) eventually oxidizes to CO\textsubscript{2} in the atmosphere and this amount can be estimated from the emissions estimates of the non-CO\textsubscript{2} gases (Seinfeld and
In national GHG inventories, inputs of CO₂ from the atmospheric oxidation of CH₄, CO, and NMVOCs are typically included in inventories for some source categories, correctly excluded for some other categories, and likely require estimating separately for yet other categories. The source categories falling into these first two groups are as follows (Gillenwater 2008):

- **Fossil fuel combustion and fuelling activities** including the atmospheric oxidation of CH₄, CO, and NMVOCs to CO₂ is accounted for by the methodology used by most countries to calculate CO₂ emissions from fossil fuel combustion. This methodology is based on fuel consumption statistics, data on the carbon content of each fuel, and oxidation factors; IPCC default carbon content or CO₂ emission factors assume that the small fraction of carbon remaining as un-oxidized solids, for example soot or ash (IPCC 1997; IPCC 2000), all carbon in the fuel is oxidized to CO₂ in the combustion process or atmosphere. For most countries that use common CO₂ factors, these inputs to the atmosphere of CO₂ from fossil fuel combustion related emissions of CH₄, CO, and NMVOCs are already accounted for under the Energy sector category 1A. The methodologies for calculating CO₂ from the atmospheric oxidation of CH₄, CO, and NMVOCs are simple and likely require estimating separately for yet other categories. The source categories falling into these first two groups are as follows (Gillenwater 2008):

- **Several managed sources of biogenic carbon (e.g., livestock)** also emit CH₄, CO, and NMVOCs. The carbon in these gases is derived from rapidly cycling (non-fossil) sources. For example, the carbon content of CH₄ from enteric fermentation is derived from plant matter, which has converted atmospheric CO₂ to organic compounds. The atmospheric oxidation of CH₄ merely completes a natural cycle and is not treated as a net anthropogenic contribution to the atmosphere's CO₂ burden. Any net changes in the biogenic carbon stocks found in plant matter are assumed to be captured under the AFOLU sector through estimates of CO₂ emissions and removals from land-use and land-use changes and forestry (i.e., biogenic carbon stock changes). Methane, CO₂, or NMVOCs are also emitted as fugitives from fossil fuel production activities such as coal mining as well as petroleum and natural gas exploration, processing and storage. The carbon emitted in the form of CH₄, CO, or NMVOCs from these fugitive emission source categories is not typically captured in fuel combustion activity data because these emissions occur prior to the collection of data on fossil fuel consumption. Therefore, CO₂ inputs to the atmosphere from the oxidation of these fugitive emissions are typically not estimated elsewhere in national GHG inventories, although fugitive CH₄ emissions are reported separately in GHG inventories.

Some industrial processes in which carbon from fossil fuel sources is used as a production feedstock (e.g., petrochemical production) may also lead to CO₂ inputs to the atmosphere. The carbon emitted in the form of CH₄, CO, or NMVOCs from these industrial processes may be included in a country's non-energy use of fossil fuel statistics or they may be estimated separately. Carbon dioxide emissions from industrial processes that use carbon feedstock as reducing agents (e.g., iron and steel production) are typically included in GHG inventories based on the assumption that the carbon in the reducing agent is fully oxidized. Depending on the assumptions and methods used to estimate storage and emissions from other non-energy use and feedstock categories (e.g., solvent use), CO₂ resulting from emissions of CH₄, CO, and NMVOCs may or may not be included elsewhere in GHG inventories.

Two options are possible to address inputs of CO₂ from CH₄ of fossil origin. Countries may apply the methods described below to calculate the mass of CO₂ oxidised. If countries use a metric for CH₄ that includes the inputs of CO₂ from CH₄ of fossil origin (such as GWP and GTP for fossil methane provided in Table 8.A.1 of Appendix 8.A in IPCC 2013), they should not estimate separately the amount of CO₂ from atmospheric oxidation of CH₄ of fossil origin to avoid double counting the warming impact. If countries choose to apply a metric which does not take into account the conversion of CH₄ into CO₂, countries should apply the methods described below to calculate the amount of CO₂ from CH₄. Countries should transparently document which option used.

The methodologies for calculating CO₂ from the atmospheric oxidation of CH₄, CO, and NMVOCs are simple and for countries that already have detailed inventories of CH₄, CO, and NMVOC emissions, no additional activity is required.
data collection should be necessary. Input of CO\textsubscript{2} to the atmosphere are calculated by converting previously estimated mass emissions of CH\textsubscript{4}, CO, or NMVOCs to CO\textsubscript{2} based on the carbon content of each gas. For example, the activity data used to estimate CO\textsubscript{2} inputs from the oxidation of emissions coal mining is already collected to estimate CH\textsubscript{4} for that category (1.B.1).

Methane, CO, or NMVOC emissions will eventually be oxidised to CO\textsubscript{2} in the atmosphere. These CO\textsubscript{2} inputs could be included in national inventories. They can be calculated from emissions of methane, CO and NMVOCs. The basic calculation principles are:

From CH\textsubscript{4}:
\[
\text{Inputs}_{\text{CO}_2} = \frac{\text{Emissions}_{\text{CH}_4} \times OF \times 44}{16}
\]

From CO:
\[
\text{Inputs}_{\text{CO}_2} = \frac{\text{Emissions}_{\text{CO}} \times OF \times 44}{28}
\]

From NMVOC:
\[
\text{Inputs}_{\text{CO}_2} = \frac{\text{Emissions}_{\text{NMVOC}} \times C \times OF \times 44}{12}
\]

Where,
\text{Inputs}_{\text{CO}_2} are the added CO\textsubscript{2} to the atmosphere from the oxidation of CH\textsubscript{4}, CO, and NMVOCs that are not accounted for already under other categories.

\text{Emissions}_{\text{CH}_4}, \text{Emissions}_{\text{CO}}, and \text{Emissions}_{\text{NMVOC}} are the emission estimates taken from other relevant emission categories (e.g., CO, NMVOC, CH\textsubscript{4} from oil and gas systems, 1.B.2).

C is the fraction carbon in NMVOC by mass (default = 0.6 for solvent use and 0.85 for other source categories; see Tables A7.2 and A7.3 and Gillenwater 2008).

OF is the oxidation factor of the carbon to carbon dioxide as a fraction. The default assumption is a value of 1. For open burning of waste in Volume 5, Chapter 5 a default value of 0.71 for OF is specified (see Table 5.2).

The carbon content in NMVOCs will vary depending on the source. Therefore, an inventory based on the speciation of the NMVOC compounds gives more accurate results.

In making these estimates inventory compilers should assess each category to ensure that this carbon is not already covered by the assumptions and approximations made in estimating CO\textsubscript{2} emissions.

See Table A7.1 for a list of the source categories relevant to the estimation of CO\textsubscript{2} from atmospheric oxidation. When identifying categories for which these CO\textsubscript{2} inputs are to be estimated, it is good practice to prevent double counting or omitting of carbon emitted to the atmosphere as CO\textsubscript{2}.

NMVOCs do not represent a single molecular species, but instead a broad range of volatile hydrocarbon species with varying molecular weights and carbon contents. Therefore, an accurate estimate of emissions of CO\textsubscript{2} from the atmospheric oxidation of NMVOCs requires a chemical speciation profile of the constituent NMVOCs (Gillenwater 2008).

To estimate CO\textsubscript{2} atmospheric inputs from NMVOC emissions the following steps may be used:

Separate the portion of national NMVOCs emissions resulting from biogenic materials from the portion of NMVOC emissions resulting from petroleum or other fossil fuel products.

Identify the portion of the fossil-based NMVOC emissions resulting from relevant energy and industrial process source categories (as determined using Table A7.2).

For the portion of these NMVOC emissions resulting from solvent use, determine the average carbon content (on a mass basis) based on a chemical speciation profile (see Table A7.3 for example). If information on the speciation profile is not available, assume a default average carbon content of 60 percent by mass. For the remaining portion of relevant NMVOC emissions from other source categories, determine carbon content values using a chemical speciation profile. If information on the speciation profile is not available, assume an average default carbon content of 85 percent by mass (Gillenwater 2008, and see Table A7.3).

There is scientific uncertainty regarding the degree to which all CH\textsubscript{4} and NMVOCs are completely oxidised to CO\textsubscript{2} in the atmosphere. There is very low uncertainty in this assumption for CO emissions. Boucher et al. 2009 assumes 95 percent of emitted CH\textsubscript{4} is oxidised, with a range of 51 to 100 percent. NMVOCs include a wide range of chemical species with atmospheric lifetimes that primarily range from minutes to months. Although, the fate of NMVOCs emitted to the atmosphere is generally oxidation to CO\textsubscript{2} through complex chemical and photochemical reactions, the fate of a fraction of some NMVOC species can be dry or wet deposition to the Earth’s surface, where the carbon they contain may escape complete oxidation to CO\textsubscript{2}. The above equations assume a complete oxidation of NMVOCs, CO and CH\textsubscript{4} to CO\textsubscript{2} in the atmosphere, however countries may apply oxidation factors less than 1, based on scientific evidence.
7.2.2 Link to relevant methodology chapters in the EMEP/CORINAIR Emission Inventory Guidebook

No refinement.

7.3 INDIRECT N₂O EMISSIONS FROM THE ATMOSPHERIC DEPOSITION OF NITROGEN IN NOₓ AND NH₃

No refinement.

7.3.1 Methodology

All anthropogenic NH₃ or NOₓ emissions are potential sources of N₂O emissions. Specific guidance on estimating N₂O emissions from that portion of nitrogen compounds associated with the volatilisation of NOₓ and NH₃ from (1) manure management systems and applied sewage sludge and (2) synthetic and organic nitrogen input to managed soils, and urine and dung nitrogen deposited by grazing animals, are provided in Section 10.5 of Chapter 10, Emissions from livestock and manure management, and Section 11.2.2 of Chapter 11, N₂O emissions from managed soils and CO₂ emissions from lime and urea application, of Volume 4 of AFOLU.

This section provides guidance on estimating N₂O emissions from the atmospheric deposition of nitrogen compounds from all other sources of NOₓ and NH₃ emissions, such as fuel combustion, industrial processes, and burning of crop residues and agricultural wastes. The method needs only to be applied where data on NOₓ and NH₃ emissions from these sources are available, e.g., from the inventories identified Section 7.2.

Equation 7.1 and EF₄ from Table 11.4, Chapter 11 of Volume 4 can be used to estimate N₂O emissions from the atmospheric deposition of nitrogen resulting from NOₓ and NH₃.

**Equation 7.1**

\[
N_2O_{(i)} = \left[ (NO_x - N_{(i)}) + (NH_3 - N_{(i)}) \right] \cdot EF_4 \cdot 44 / 28
\]

Where:

- \(N_2O_{(i)}\) = N₂O produced from atmospheric deposition of N from NOₓ and NH₃ emissions from source \(i\), in Gg
- \(NO_x-N_{(i)}\) = nitrogen content of NOₓ emissions from source \(i\) assuming that NOₓ is reported in NO₂ equivalents (Gg NOₓ-N or Gg NO₂ • 14/46)
- \(NH_3-N_{(i)}\) = nitrogen content of NH₃ emissions from source \(i\) (Gg NH₃-N or Gg NH₃ • 14/17)
- \(EF_4\) = emission factor for N₂O emissions from atmospheric deposition of N on soils and water surfaces (kg N₂O-N/kg NH₃-N or NOₓ-N emitted)

The activity data NOₓ-N \(_{(i)}\) and NH₃-N \(_{(i)}\) are taken from the inventories as identified in Section 7.2, if available.

This method assumes that N₂O emissions from atmospheric deposition are reported by the country that produced the original NOₓ and NH₃ emissions. In reality, the ultimate formation of N₂O may occur in another country due to atmospheric transport of emissions. The method also does not account for the probable lag time between NOₓ and NH₃ emissions and subsequent production of N₂O in soils and surface waters. This time lag is expected to be small relative to an annual reporting cycle.

8 In addition to being redeposited on soils and surface waters, NH₃ can also lead to the formation of N₂O from atmospheric chemical reactions. However, there is currently no method available for estimating conversion of NH₃ to N₂O in the atmosphere.
7.3.2 Quality Assurance/Quality Control, Reporting and Documentation

No refinement.
